ABSTRACT

The eigenvalue degeneracy problem inherent in the discrete Fourier transform (DFT) matrix operator and the development of a full basis of orthogonal eigenvectors have been addressed via a commuting matrix, devoid of the aforementioned eigenvalue degeneracy problem, that also serves as a discrete version of the Gauss-Hermite (G-H) differential operator.

This G-H operator is however, is not bandlimited, and existing discretization efforts run into distortion problems that manifest as deviation from the ideal linear eigenvalue spectrum, aliasing in the eigenvectors, and as a non-invertible peak to parameter mapping associated with the discretization restricting its ability to uniquely represent multicomponent chirp signals. Existing approaches do not account for the effects of windowing on discretization.

In this paper, we focus on distortion issues associated with the discretization of the G-H operator and their sources. We specifically analyze the discrete version of the G-H operator based on quantum mechanics in finite dimensions (QMFD), by computing its underlying peak to parameter mapping and its invertibility to subsequently present a representation of the operator with improved mapping invertibility via use of suitable windowing of the eigenvalue spectrum.

Keywords: discrete Fourier transform, eigenvectors, discrete Fractional Fourier transform, aliasing, peak to parameter mapping, quantum mechanics in finite dimensions, windowing.

1. DISTORTION SOURCES

In recent years, the fractional Fourier transform (FRFT) has become a very useful tool for time-frequency analysis for signals with modulation [2]. The kernel of the continuous-time FRFT [2] is given by:

\[ K_\alpha(t, u) = \sqrt{\frac{1 - j\cot \alpha}{2\pi}} \exp \left( j(t^2 + u^2) \cot \alpha / 2 - jtu \csc \alpha \right) \]

The corresponding Mehler’s expansion for the chirped kernel is:

\[ K_{\alpha \omega}(u) = \sum_{k=0}^{\infty} \exp(-j\kappa \alpha) h_k(t) h_k(u), \]  

where \( h_k(t) \) denoted the \( k \)-th Gauss-Hermite (G-H) function. This chirped kernel produces a Dirac impulse for the FRFT, when the input signal is a chirp signal with a specified center-frequency \( \omega_0 \) and chirp rate \( \alpha \) for a specific angle \( \alpha_0 \):

\[ X_{\alpha \omega}(u) = \exp \left( j \frac{\cot \alpha_0}{2} u^2 \right) \sqrt{\frac{1 - j \cot \alpha_0}{2\pi}} \times 2\pi \delta(\omega_0 - u \csc \alpha_0) \text{ for } \alpha_0 = \cot^{-1}(\frac{1}{2\alpha}). \]

This chirped kernel of the FRFT is however, not bandlimited, and causes distortion in discrete versions of the FRFT. Existing commuting methods for computing the discrete version of the FRFT (DFRFT) [4, 5, 3] use a eigenvalue decomposition of the form:

\[ A_{\alpha}(x) = \mathcal{V} \mathcal{A}^{\frac{\alpha}{2}} \mathcal{V}^T x = \sum_{k=0}^{N-1} \exp(-j\kappa \alpha) \mathcal{V}_k \mathcal{V}^T_k x, \]

where \( \mathcal{V} \) is a fully orthogonal basis of DFT or CDFT eigenvectors, obtained from a commuting matrix, that serve as discrete counterparts of the G-H functions. As seen in earlier work [8], the effects of discretization results in a non-invertible peak to parameter mapping restricting the capabilities of the DFRFT.

2. SOURCES OF DISCRETISATION ERRORS

From Eq. (1) and Eq. (2), we can observe that in the transition from the continuous to the discrete FRFT, there are two phenomena happening:

1. Truncation or windowing of the IIR eigenvalue sequence of the G-H operator with a rectangular window of duration \( N \) samples:

\[ \lambda_{\alpha}[k] = \exp(-j\kappa \alpha) w[k], \]

where \( w[n] \) is the \( N \)-point boxcar window [1]. This is analogous to the window based FIR filter design technique, where a IIR impulse response is approximated with an FIR windowed equivalent or spectral analysis using the DFT. This will result in spectral distortion of the eigenvalue sequence:

\[ \Lambda_{\alpha}(e^{j\omega}) = W(e^{j\omega - \alpha}), \]

where \( W(e^{j\omega}) \) denotes the DTFT of the window function [1] used. The boxcar window produces the narrowest main lobe but has the smallest main lobe to sidelobe spectral amplitude ratio, thereby producing more sidelobes in the DTFT of the windowed eigenvalue sequence. Existing approaches towards G-H operator discretization, however, do not accommodate windowing effects.

This research was supported by the United States Department of Energy (Award DE-NA 0002494) and the National Nuclear Security Administration (NA-221)
We first focus our attention on the QMFD approach in [3, 7]:

The eigenvalue sequence of the diagonal operator gives rise to improvements with a reduced degree of distortion. We further show through source analysis that result in a commuting matrix and associated eigenvectors that arise in the G-H operator discretization and in particular, incorporate the use of different windows on the diagonal matrix $Q^2$. Windowing using an appropriate data window reduces the deviation from a linear eigenvalue spectrum at the tail-end of the eigenvalue spectrum.

2. Discretization or sampling of the G-H functions to yield DFT/CDFT eigenvectors which in turn result in spectral aliasing in the eigenvectors corresponding to the higher G-H modes with frequency content at the edges of $|\omega| < \pi$:

$$V_k(e^{j\omega}) = \frac{1}{T_s} \sum_{k=-\infty}^{\infty} H_k \left( \frac{\omega - 2k\pi}{T_s} \right), \ |\omega| < \pi,$$

where $T_s$ is the sampling period associated with the discretization of the G-H functions.

Several commuting matrix approaches towards furnishing the unitary basis of DFT/CDFT eigenvectors have been studied [4, 5, 3] staking the claim that they are discrete versions of the G-H operator.

In this paper, we focus on the distortion issues identified above, that arise in the G-H operator discretization and in particular, incorporate windowing effects into the QMFD approach [3]. We further investigate extensions of the QMFD approach [3, 7], in light of these sources, that result in a commuting matrix and associated eigenvectors with a reduced degree of distortion. We further show through simulation results that a suitable choice of window applied to the eigenvalue sequence of the discrete operator results in improvement of the invertibility of the underlying peak to parameter mapping and to the associated mean squared errors of chirp parameter estimates that are of importance in SAR vibrometry applications [9, 10].

3. QMFD APPROACH: DIAGONAL $Q$ AND QUASI-TOEPLITZ MATRICES

We first focus our attention on the QMFD approach in [3, 7]:

$$Q = \sqrt{\frac{2\pi}{N}} \text{diag}(-m, \ldots, m)$$

$$P = WQW^H$$

$$T = P^2 + Q^2,$$

(3)

where $Q$ and $P$ denote the finite dimensional position and momentum operators and $W$ denotes the centered version of the DFT:

$$W_{rs} = \frac{1}{\sqrt{N}} \exp \left( -j \frac{2\pi}{N} (r-m)(s-m) \right), \ 0 \leq r, s \leq N-1$$

with $m = (N-1)/2$. As was shown in [3], for the matrix $T$ to commute with either version of the DFT, the matrix $Q^2$ needs to be $W^2$-centro-symmetric:

$$W^2Q^2W^2 = Q^2,$$

If we further require the commutator $C = [Q, P]$ to commute with the DFT, this implies that we require the matrix $Q$ to be $W^2$-anti-symmetric [3]:

$$W^2QW^2 = -Q.$$

Here we specifically focus on the elements of the matrix $P$:

$$P_{rs} = \sum_{l=0}^{N-1} \sum_{m=0}^{N-1} W_{rl} Q_{lm} W_{ms}^*$$

(4)

Substituting the diagonal form of $Q$ into this expression yields:

$$P_{rs} = \sqrt{\frac{2\pi}{N}} \sum_{l=0}^{N-1} (l-m) \exp \left( -j \frac{2\pi}{N} (l-m)(r-s) \right).$$

(5)

Specifically the matrix $Q$ is non-diagonal, is purely imaginary because its elements are the DFT of an odd function. The matrix $Q$ is also Toeplitz since the matrix elements depend only on $(r-s)$. In a similar fashion, we can evaluate the matrix elements of the commuting matrix $T$ via:

$$T_{rs} = \frac{2\pi}{N} \left\{ \frac{1}{l=0}^{N-1} (l-m)^2 \exp \left( -j \frac{2\pi}{N} (l-m)(r-s) \right) \right\}$$

$$T_{rs} = \begin{cases} \frac{2\pi}{N} \sum_{l=0}^{N-1} (l-m)^2 \exp \left( -j \frac{2\pi}{N} (l-m)(r-s) \right) & r \neq s \\ \left( (r-m)^2 + \sum_{l=0}^{N-1} (l-m)^2 \right) & r = s \end{cases}$$

The following symmetries can be inferred from the matrix elements:

1. for the diagonal form of the $Q$ matrix and either form of the DFT, either the centered or the regular, the underlying commuting matrix has almost-Toeplitz symmetry.

2. Only main diagonal elements are different and follow a square law in accordance with the $W^2$-symmetry about $r = m$ along the diagonal for the centered DFT and $W^2$-symmetry about $r = m + 1$ along the diagonal for the DFT.

3. The commuting matrix will also have $J$-symmetry about $r = m$ along the diagonal for the centered DFT and $W^2$-symmetry about $r = m + 1$ along the diagonal for the DFT.

4. The commuting matrix is further positive semi-definite:

$$x^H T x = x^H (P^2P + Q^2Q)x = ||Px||^2 + ||Qx||^2 \geq 0$$

This motivates the equivalence of the commuting matrix $T$ to the auto-correlation matrix of a weakly non-stationary time-series with elements:

$$\frac{2\pi}{N} \sum_{l=0}^{N-1} (l-m)^2 \exp \left( -j \frac{2\pi}{N} (l-m)(r-s) \right) \quad r \neq s$$

$$\frac{2\pi}{N} (r-m-1)^2 + \frac{2\pi}{N} \sum_{l=0}^{N-1} (l-m-1)^2 \quad r = s$$

$^1$A Toeplitz operator will produce a purely stationary basis of eigenvectors comprised of cosines and sines.
These quantities in the DFT basis are obtained via similarity transform
specifically the vectors of the DFT or the CDFT obtained from the previous section.

The time-series viewpoint also explicitly describes the windowing effects on the elements of the quasi-Toeplitz commuting matrix. Specifically the elements of the $Q^2$ matrix are windowed with a rectangular window of duration $N$ samples:

$$Q^2_w = A_w Q^2,$$  \hspace{1cm} (6)

where $A_w$ is a diagonal matrix with the window samples along the diagonal. By an appropriate choice of the window, we can affect the eigenvalue spectrum of the commuting matrix as depicted in Fig. (1), where we use a Kaiser window of duration $N = 256$ and parameter $\beta = 1.2$. The Kaiser window is chosen due to the degree of freedom that the parameter $\beta$ affords in main lobe to side lobe trade-off. This has the effect of smoothing the fluctuations in the eigenvalue spectrum at the tail end as evident from Fig. 2 and expanding the region of the invertibility of the peak to parameter mapping [8]. To further reduce the distortions resulting from the truncation of the eigenvalue sequence of the G-H operator we now consider the case of the non-diagonal $Q$, where we force the DFT commuting matrix to possess a linear eigenvalue spectrum.

### 4. QMFD APPROACH: NON-DIAGONAL Q CASE

As described in [7], the QMFD method needs to be modified so that the equations of motion are satisfied in the centered-DFT or regular-DFT basis. This is based on the observation that the $Q$ and $P$ tri-diagonal basis corresponds to a diagonal number operator and a diagonal DFT operator. To obtain the number operator in the centered DFT basis or the regular DFT basis we similarity transform via the eigenvalues of the DFT or the CDFT obtained from the previous section. Specifically the $Q$ and $P$ tri-diagonal matrices in the $N$-diagonal basis or the DFT diagonal basis are:

$$Q_o = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 & 1 & 0 & 0 & \ldots \\ 1 & 0 & \sqrt{2} & 0 & \ldots \\ \vdots & \vdots & \vdots & \vdots & \ddots \\ \end{pmatrix}$$

$$P_o = \frac{j}{\sqrt{2}} \begin{pmatrix} 0 & 1 & 0 & 0 & \ldots \\ -1 & 0 & \sqrt{2} & 0 & \ldots \\ \vdots & \vdots & \vdots & \vdots & \ddots \\ \end{pmatrix}$$

The number operator in this tridiagonal representation is just the diagonal matrix:

$$N_o = \text{diag}(1, 3, 5, 7, \ldots, 2N-1)$$  \hspace{1cm} (7)

These quantities in the DFT basis are obtained via similarity transformation using the DFT eigenvectors $V$ obtained from the previous section:

$$Q_{new} = V Q_o V^H \quad \text{and} \quad P_{new} = V P_o V^H$$  \hspace{1cm} (8)

The corresponding number operator in the DFT basis is:

$$T = P_{new}^H Q_{new}^H Q_{new} = P_{new}^H + Q_{new}^2 = V N_o V^H,$$  \hspace{1cm} (9)

where $V$ are the orthogonal or unitary DFT eigenvectors obtained via the previous section with the almost-Toeplitz number operator. This transformed number operator by construction has a odd integer eigenvalue spectrum, and its eigenvectors are the DFT eigenvectors. This matrix therefore commutes with the appropriate DFT:

$$TW = WT \quad \text{or} \quad [W, T] = 0.$$

The transformed number operator is however, not almost-Toeplitz as in the previous section but a $W^2$-symmetric matrix corresponding to a non-diagonal $Q_{new}$ matrix:

$$W^2 TW^2 = TW^4 = T,$$  \hspace{1cm} (10)

where we have used the observation that $[W, T] = 0$. Since the new number operator was constructed from the eigenvectors from the previous almost-Toeplitz framework, they carry with them the distortion due to truncation and aliasing. However, the distortion is reduced, in that the eigenvalue spectrum is closer to that of the G-H operator than what was obtained in the previous framework, thereby reducing one of the sources of distortion discussed in the introduction section. The characteristic feature of this approach is that we are specifying the eigenvalue sequence of the commuting matrix to be the truncated odd numbered spectrum. We can further reduce the effects of windowing of the eigenvalue sequence by choosing the window so that the eigenvalue sequence is:

$$\lambda_w[k] = (2k + 1)w[k], \quad 0 \leq k \leq N - 1,$$

where $w[k]$ is an appropriately chosen window [1] that minimizes the effects of eigenvalue truncation. Figure 3 compares the peak to parameter mapping underlying both the diagonal $Q$ approach and the non-Toeplitz framework for $N = 256$ using the Kaiser window. The mapping depicts a slight improvement in terms of invertibility of the mapping from $84.55$ percent to $85.33$ percent. This improvement is attributable to the fact that the eigenvalue spectrum in the non-diagonal $Q$ case accommodates the effects of eigenvalue truncation.

Figure 4(a) depicts the DFRFT spectra for a chirp signal for different values of the Kaiser window parameter $\beta$. For $\beta = 15$ with the non-diagonal $Q$ formulation, we observe that there is significant distortion of the peaks arising from truncation. As can be observed specific values of the $\beta$ parameter result in steeper slopes on the peaks of the underlying DFRFT spectrum. From Figure 4(b,c) we observe that the slopes of the spectral peaks are much steeper for $\beta = 1.2$ than for $\beta = 0.001$. Figure 4(d) depicts the eigenvalue spectrum corresponding to the different values of the Kaiser window parameter.

Figure 5(a) depicts the percentage invertibility associated with the $Q$-windowing approach, the eigenvalue windowing approach, and the joint windowing approach using a Kaiser window with parameter $\beta = 1.2$. As can be observed, the joint windowing approach improves the invertibility of the peak to parameter mapping in relation to the other options. Furthermore, the improvement offered by the windowing approach is more significant for smaller transform sizes $N$, due to the fact that the distortion due to truncation effects is more significant for these smaller values for $N$, where the invertibility approaches $91\%$ for larger matrix sizes $N$. Invertibility of the mapping as pointed out in [8] impacts the MSE of the corresponding chirp parameter estimates.
Fig. 2. Peak to parameter mappings for $N = 256$: (a) quasi-Toeplitz framework, and (b) non-diagonal $Q$ formulation for the minimum-norm approach. The invertibility percentage of the mappings corresponding to the two operators are 84.55 percent and 85.33 percent respectively. The continued presence of a non invertible region in the mapping is a consequence of the truncation and aliasing distortion discussed in the introduction.

Fig. 3. Effect of windowing eigenvalue sequence: (a) DFRFT spectrum magnitude for Kaiser window with $N = 256$, $\beta = 15$, (b) DFRFT spectrum magnitude for Kaiser window with $N = 256$, $\beta = 0.001$, (c) DFRFT spectral magnitude for $\beta = 1.2$, and (d) eigenvalue spectrum with different Kaiser window parameters. Note that we obtain steeper slopes on the peaks of the DFRFT magnitude spectrum for $\beta = 1.2$ and for $\beta = 15$ we observe a significant amount of aliasing.
5. CONCLUSION

In this paper, we studied the problem of discretizing the Gauss-Hermite operator and the two basic sources of distortion: (a) eigenvalue truncation resulting in spectral distortion of the eigenvalue sequence, and (b) sampling of the eigenfunctions resulting in eigenvector aliasing. We studied two classes of matrices that commute with either the centered DFT or the regular DFT in the context of the QMFD method developed in [3] in terms of the distortion introduced in the transition from the continuous to the discrete FRFT.

We first studied the quasi-Toeplitz framework where the corresponding Q matrix is diagonal and developed a weakly non-stationary time-series viewpoint to expose distortion due to discretization in the approach. Means to minimize this distortion, such as windowing of the diagonal Q matrix with an appropriately chosen window function were studied. We then incorporated eigenvalue windowing into the more general approach to mitigate truncation effects at the end of the eigenvalue spectrum. A Kaiser windowed version of the truncated odd integer eigenvalue spectrum, resulted in sharper peaks in the underlying DFRFT spectra in comparison to the boxcar windowed spectra and eventually translated to a wider invertibility region for the peak to parameter mappings. Improvement from windowing is specifically more pronounced for smaller matrix sizes, where the distortion from discretization is more pronounced.
