Hardware Trojans (HT)

What is a hardware Trojan?
A deliberate and malicious change to an IC that adds or removes functionality or reduces reliability

- The modifications may be designed to leak sensitive information, personal or corporate
- The modifications may be designed to cause a system to fail at a critical time while operating in mission mode
- The modification may be designed to reduce the reliability of the IC

What makes this a challenging problem?
Adversary makes purposeful discovery highly improbable & physical inspection is very expensive
HT Example
Missile control system
Assume a chip receives encrypted commands from an RF channel and stores the value in a register for subsequent decryption.

Adversary transmits "code" that causes activation - missile detonates before reaching its target.
Adversary may try a ’stealthier’ strategy, e.g., a ’monolithic NAND gate’

Many other implementations are possible, e.g. pass-gate versions, some better than others at minimizing power supply anomalies.
Insertion Points

The horizontal dissemination of the IC design, fabrication and test processes to many distinct companies has dramatically increased the potential for malicious activities:

- Designing third party IP blocks
- Developing CAD tool scripts
- Integration activities where IP blocks and glue logic are assembled into SoCs
- Behavior synthesis and place and route (PnR) carried out by CAD tools
- Layout mask data generation and mask preparation
- Process parameter control mechanism used in the multi-step fabrication process
- Supply chain transactions associated with transferring wafers between facilities
Insertion Points

- Generating test vectors using automatic test pattern generation (ATPG)
- Wafer-probing activities for measuring test structures and detecting defects
- Supply chain transactions associated with creating and transferring dice
- Processes responsible for packaging ICs
- Applying ATPG vectors to packaged ICs using ATE
- Supply chain transactions associated with transferring packaged parts
- Printed circuit board (PCB) design and fabrication
- Processes responsible for installing PCB components (populating PCBs)
- System integration and deployment activities
**Insertion Points**

The wide range and widely distributed nature of these activities presents an overwhelming opportunity for subversion.

Moreover, the wide diversity among the tasks will require a very sophisticated and complex system to manage the entire set of trust vulnerabilities from start to finish.

The research community is tackling these trust challenges one-at-a-time, focusing on those that are the most attractive insertion points for adversaries:

- **Subversion of IP blocks** is a serious concern given the ease in which malicious functionalities can be covertly inserted.
  
  Moreover, the absence of alternate representations and models for comparison compounds the challenge.

- **Layout modifications and IC fabrication** insertion points represent another important focus area.
  
  Challenges here include the huge complexity associated with analyzing fabricated ICs and the wide range of opportunities available to the adversary.
**HT Scenarios: Soft-IP Trojans**

Adversary can compromise **soft-IP** by inserting extra, hidden functionality into the netlist

**Implications**

- No golden model is available
- Every IC has the HT

**Detection strategies include**

- **Formal verification methods**
  
  Prove that the functionality of the IP is equivalent to some higher-level, more abstract ‘trusted’ specification

  Unfortunately, formal verification is only applicable to small circuits, i.e., components of the design

  There has been a lot of recent work in this area that offers alternative solutions, e.g., circuit obfuscation techniques, which we will cover later in this course
HT Scenarios: Hard- and Soft-IP Trojans

- **Monitoring the IC using a 'trusted companion IC’**
  
  Trusted companion IC has access to the internal state of the untrusted IC through extra pins/scan chain.
  
  Trusted companion IC is ’programmed’ such that it knows the *legal state space* of the untrusted IC, and sets off an alarm and/or shuts down the IC if violated.

  This technique can also be used for GDS-based HT.

High security applications would likely use only IP developed in-house or from trusted sources.

**Hard-IP Trojans**

The insertion point here is the layout (GDS).

We mentioned earlier that several modifications are possible, e.g., those designed to 1) disable/destroy, 2) to leak information and 3) decrease reliability.
**HT Scenarios: Hard-IP Trojans**

Changes to the IC’s function can be implemented by

- Using existing ’white-space’ (places in the layout where there are no transistors or where there is a by-pass capacitor)
- ’Nudging’ gates to make space for the HT gates

In case you were thinking about adding some type of verifiable white space filler to prevent the first case from occurring

Parametric changes designed to reduce reliability can be implemented by thinning wires to accelerate EM effects, by thinning oxide to accelerate TDDB, etc.

I would like to argue that when **direct control** is needed by the adversary, then **functional modifications** (the first type) are more attractive

Why do you think this might be the case?

Let’s consider another HT parameter, the **size** of the HT

HT can be very small and be effective, e.g., only a couple/three gates

For HT designed to change functionality, small HT are risky - why?
**HT Scenarios: Hard-IP Trojans**

Therefore, I argue that HT designed to change functionality, e.g., destroy/disable/enable remote control, etc., are likely to be larger, 10’s to 100’s of gates to prevent discovery.

Unfortunately, the same is not true for **information leakage** HT. Since they do not, at least in an obvious way, change functionality, they can be very small and remain secure against detection.

Information leakage HT can ’leak’ information in ways that are not easily detected:

- By broadcasting data as EM radiation using a portion of the power grid
- By inserting data into a communication channel, that appears as error bits to a valid receiver
- By inserting data into a communication channel at a higher frequency, e.g., baud rate, than the valid receiver is expecting

Lot’s of strategies have been proposed -- all of them difficult to detect and in many cases, require non-traditional testing methods.
**HT Scenarios: Hard-IP Trojans**

Unlike manufacturing defects, you only need to detect ONE HT to yield success!

For example, if a layout-based HT is inserted in EVERY copy of a manufactured IC, then alternative test strategies that use MUCH larger test sets can be used.

Unfortunately, layout-based HT can be inserted in only a subset of the ICs (unlike soft-IP Trojans which are, by definition, in every copy).

This makes it more difficult to develop a testing method to detect them - why?

Whether the HT is *selectively inserted* or inserted into every copy depends on the application.

I argue that functionally disruptive HT, like the missile HT, are likely to be inserted into every copy of an IC -- why?

I also argue that information leakage HT do **not** need to be inserted into every copy of the IC to be useful -- why?
**Important Considerations**

Note that significant differences exist in the HT countermeasures and detection strategies that are applicable

This is true even when only considering only the Soft-IP and Hard-IP insertion points discussed above

For example, golden models are not available at the soft-IP block insertion point, but architectural changes that **obfuscate** the design are available as countermeasures

In contrast, the Hard-IP insertion point allows layout design data to be used to validate the functional and analog behaviors of the IC

But obfuscation is limited to ‘dummy via’ insertion and other nano-level manipulations of the design

Also, side channel information is not available or is not accurate enough to be useful for soft-IP blocks but is very powerful for layout-level HT detection
Summary of Challenges of Detecting Soft-IP and Hard-IP Trojans

As discussed, HT detection faces several challenges:

- **Hard-IP Trojans Only:** The adversary can choose to ‘selectively’ insert the HT into only a subset of the manufactured ICs, making it necessary to verify all manufactured ICs.
- **HT designed to leak information** may not cause a change in the functional behavior and therefore, will require alternative testing methods.

Additional challenges associated with HT detection:

- **Task of identifying an HT** is akin to *finding a needle in a haystack*, i.e., trusted authority must find unknown malicious function in a ‘sea’ of functions and gates.
- **HT and ‘bugs’ share many of the same characteristics,** and it is widely accepted that finding all the bugs is generally infeasible.
- **Any attempt by the trusted authority to increase the ‘ease’ of HT detection** may be visible to the adversary, i.e., the adversary can avoid the countermeasures.
- **The appropriate detection strategy will vary greatly depending on the assumptions made regarding the “insertion point”,** e.g., Soft-IP vs Hard-IP Trojans.
Summary of Challenges of Detection HT

The only advantage afforded to the trusted authority is that his/her detection strategy can be **parallelized** because the HT needs to be detected only once.

Manufacturing tests can be partitioned among multiple ATE.

Note this assumes that *selective HT insertion* is not possible.

Is always true for Soft-IP Trojans and is a reasonable assumption for Hard-IP Trojans b/c of mask cost issues.

Unfortunately, even high levels of parallelism ‘run-out-of-gas’ when the full extent of the search space, both combinational and sequential, is considered.
Hard-IP Trojan Taxonomy

Layout inserted (GDS) Trojans can take many forms but can be broken into the following categories:

- **Trojan classification**
  - Physical characteristics
    - **Type**
      - Functional
      - Parametric
    - **Size**
      - Small Transistor/wire
      - Large Gate/Macro
    - **Distribution**
      - Tight
      - Loose

- **Activation characteristics**
  - Always on
  - Condition based
    - Sensor based
      - Temp.
      - Volt.
      - Ext.
  - Logic based
    - Input
      - Internal state
        - Cnter/Ck
      - Data
      - Instruction
      - Interrupt
    - Defects
    - Reliability

- **Action characteristics**
  - Modify function
    - Add
    - Bypass
    - Modify spec.

Hard-IP Trojan Detection Strategies

Three basic approaches:

- **IC Deprocessing and Application of Failure Analysis Methods**
  The most straightforward approach is to ‘deprocess’ the chip, i.e., remove one layer at a time and compare the wires and transistors with the original layout.

  The comparison can be implemented using image processing methods that compare micro-photographs of IC geometries with layout images.

  Failure analysis (FA) methods traditionally used for identifying the root cause of failure in IC can also be applied to extract geometries.
  - Scanning Optical/Electron Microscopy (SOM/SEM)
  - Pico-Second Imaging Circuit Analysis (PICA) and Voltage Contrast Imaging
  - Light-Induced/Charge-Induced Voltage Alternation (LIVA/CIVA)

- **Advantages: IC Deprocessing and Application of Failure Analysis Methods**
  Potentially highly sensitive to the presence of HT.

- **Drawbacks: IC Deprocessing and Application of Failure Analysis Methods**
  Destructive, may miss selectively-inserted HT, cost, effectiveness in nano...
Hard-IP Trojan Detection Strategies

Three basic approaches:

- **Functional activation** through logic testing

  Develop an automatic test pattern generation (ATPG) strategy that generates logic vectors (patterns) to activate the HT

  Given the connectivity characteristics of the HT to the original circuit are unknown, ATPG must be based on a heuristic

  The heuristic chosen by most researchers is that the adversary is likely to connect the HT to wires in the original design that are the most difficult to control and observe

  The rational for this is simple: the adversary wants to make *accidental discovery*, i.e., through manufacturing test, of the HT extremely unlikely

  Therefore, many of the proposed *functional activation* strategies are based on deriving tests for nodes that are *random-pattern resistant*. 
**Hard-IP Trojan Detection Strategies**

Three basic approaches:

- **Functional activation** through logic testing
  
  *Random-pattern resistant* is a term used in the testing community for nodes that have a low probability of being tested using a set of random patterns.

  Controllability and Observability analysis of these nodes indicates that these nodes are controlled and/or observed under very specific conditions.

  These *rare* conditions, i.e., internal circuit states, are the target of many of the proposed HT testing strategies.

  The premise is that the adversary can determine these *hard-to-detect* nodes using standard manufacturing test tools and connect the HT to them.

- **Advantages: Functional activation** through logic testing

  Existing manufacturing test tools can be leveraged.

  The presence of the HT can be validated without deprocessing.
Hard-IP Trojan Detection Strategies

Three basic approaches:

- **Drawbacks: Functional activation** through logic testing
  
  Only applicable to small, functional HT (least likely) -- information leakage HT may **not** change the functional behavior of the IC

  The adversary may guess that the ATPG strategy may be directed at *hard-to-detect* nodes and can connect some HT inputs to *easy-to-detect* nodes

  Generating test patterns may be extremely time consuming or impossible for some *hard-to-detect* nodes (impossible to activate)

  As the number of inputs to the HT increases, the difficulty of generating HT activation patterns increases dramatically
  
  This is true because ATPG must generate patterns that check **all combinations** of *hard-to-detect* nodes (not just one node at a time as is true in manufacturing test for detects)
Hard-IP Trojan Detection Strategies

Three basic approaches:

- **Parametric Anomaly Detection Strategies**
  
  A parametric anomaly is a change in the analog characteristics of the IC, e.g., in its power consumption, delay characteristics, temperature profile, EM radiation characteristics, etc.

  As we indicated earlier with the HT missile example, adding a HT, i.e., a set of gates, to the layout of an IC changes the analog characteristics of the IC

  These changes include:
  - Increasing the leakage characteristics of the IC
  - Increasing the dynamic power consumption of the IC
  - Increasing the delay of paths that have nodes connected to the HT gate inputs
  - Temperature profile changes in the IC, etc.

  Therefore, HT detection methods can be developed that measure an IC’s analog characteristics (*signature*) and compares it against a ’golden device’
Hard-IP Trojan Detection Strategies

Three basic approaches:

- **Parametric Anomaly Detection Strategies**

  The golden device *signature* can be generated from models of the IC using simulation experiments.

  The challenge in making this approach effective is accounting for the natural variations that occur between chips that are introduced by:
  - Test environment variations, e.g., probe card resistance variations
  - Noise sources, e.g., environmental, instrumentation-related, on-chip sources
  - Process variations

  Detection of selectively-inserted HT may be possible by comparing responses among chips.

- **Advantages: Parametric Anomaly Detection Strategies**

  Non-destructive and much more cost-effective than FA methods.
Hard-IP Trojan Detection Strategies

Three basic approaches:

• **Advantages: Parametric Anomaly Detection Strategies**
  
  Can potentially detect ALL types of HT, including functional, information leakage and reliability HT

  Can be extremely sensitive to small anomalies if the appropriate *calibration* methods are applied to reduce or eliminate test environment and process variations

• **Drawbacks: Parametric Anomaly Detection Strategies**
  
  Automatic test equipment (ATE) instrumentation may need to be customized to make analog measurements, e.g., transient current and path delay

  Data collection may be time consuming and storage intensive, e.g., multiple strobes of the capture cycle to measure *actual* path delays
Hard-IP Trojan Detection Strategies

Three basic approaches:

- **Drawbacks: Parametric Anomaly Detection Strategies**
  
  Developing an adequate *golden device* model(s) may be difficult
  
  Models need to include environmental variations and process variations if chip data is not *calibrated*

  
  Number of *false alarms* may be large if process variations are not accounted for
  
  Validation through deprocessing make false alarms very costly
